**KEPLERIAN ORBIT C++ MODEL**

Prepared by	S. Carnahan
-------------	-------------

<b>Status:</b> Tested
<b>Scope/Contents</b>
The Keplerian orbit class is an object oriented keplerian orbit. Given a planet and orbital elements it can provide a host of outputs including orbital period and position and velocity.

## 1 Model Description

This model provides a coherent set of data and functionality to represent a Keplerian orbit.

## 2 Model Functions

This module contains several functionalities described below

- **Interface: Orbit Elements** Classic Orbit elements are provided to define the orbit. Individual elements can be changed.
- **Interface: Outputs** Classic orbital properties like angular momentum and energy can be accessed as functions using variable names common in such tests as Vallado. For example, specific orbital angular momentum is accessed via the member method `h()`.

## 3 Model Assumptions and Limitations

- **Limitation: Elliptical Orbits** In its current incarnation, this module supports only elliptical orbits. Future work should expand the class to include parabolic, hyperbolic, and circular orbits.

## 4 Test Description and Success Criteria

The unit test `test_unitKeplerianOrbit.py` tests the construction and calculations of the class. It specifically checks the mean motion, orbital period, and position and velocity outputs. The test PASSED.

## 5 User Guide

This module was meticulously set up to ensure that all variables can only be set or retrieved by setter and getter functions. If the module is instantiated without arguments, the spacecraft is in some arbitrary orbit. Generally, it should be called with the first argument as the desired orbital elements and the second argument as a `GravBodyData` object.
